Abstract

Termites are problematic insects due to their threat in agricultural fields and human settlements. They cause a significant loss to food and cash crops, wooden components in buildings and trees of economic importance, especially in warm environments of subtropical and tropical regions. For a long time, termite attack has been controlled using different chemical methods, though they cause human health and environmental problems. This review has been focused on termite diversity, damage caused by termites in crop plants and other infrastructures as well as three eco-friendly alternative methods such as insecticidal plants, biological method and cultural control. Methods discussed under cultural approach include animal by-products, dead animals, meat and sugarcane husks, wood ashes and intercropping system. For biological method the focus is on nematode, bacterial and fungal application while the insecticidal plants highlighted on the potential of Cupressus lusitanica, Tephrosia vogelli, Eucalyptus dalrympleana, Lantana camara and Azadirachta indica in the control of termites.

Keywords: Biological method, insecticidal plants, insect pests, termites.

Introduction

Termites are insects which usually possess a stable and an organized colony in warm terrestrial environments. They contribute significantly to the ecosystems of the world through decomposing wooden components. Termite activities in the soil lead to excellent aeration and improvement of soil nutrients by adding Nitrogen (N) and Carbon (C) through Nitrogen (N) fixation and Carbon (C) mineralization respectively. They are known primarily for their damage to woody plant parts and constrain crop production. In addition, they attack wooden structures of buildings and inhibit production of trees of economic importance to mostly African communities’ farms, global tropical and subtropical areas. The most known problematic termites species are Heterotermes, Psammotermes and Coptotermes (family Rhinotermitidae), Hodotermes and Anacanthotermes (family Hodotermitidae), Neotermes sp. (family Kalotermitidae) as well as Syntermes, Procornitermes, Odontotermes, Microtermes, Macrotermes, Cornitermes, Ancistrotermes and Amitermes (family Termitidae). Apart from causing crop damage and individual hardship to life, approximately $ 40 billion was used to buy synthetic pesticides purposely to manage termites and repair destroyed wooden property in 2010 globally. African countries like Mozambique, Zambia, Uganda and Malawi had cases where maize were destroyed by termites before and after harvesting, while in Nigeria, Burkina-Faso, Niger and Mali at most 30% of harvested groundnuts were reported to be damaged by termites in 1996.

In East Africa, particularly Tanzania, damage by termites to both young and mature coconuts during dry seasons were reported. In light of the above, there is a need to test and evaluate the less costly and reliable termite management strategy so as to encourage households and small scale farmers to engage in crop farming. In fact, having a sustainable way of controlling termites will result in the reduction of hunger in developing countries especially African countries where the problem of hunger has been reported most of times.

African Termite diversity

Favorable condition of Africa is the major reason for high abundance of termites with more than 664 termite species diversity recorded in the continent. High abundance of termite animals has been documented from southern, western and eastern Africa, with few species recorded in Northern Africa. In this study termite diversity has been described based on their morphology. Morphology is characterized by using body color (pale, grey, brown and red-black), body size (large or small), large and small heads with mandible position as well as soft and hard cuticle. For example, in genus Macrotermes, species labeled A, B, C, G and H (Figure-1) differ among themselves in color with respect to their locations.
Therefore, few images compiled in Figure-1, justify that regions of Africa have high diversity of termite species and therefore, demands more studies to identify unknown ones.

Damage caused by termites in crop plants

Susceptible crop plants to termite pests in Africa include groundnuts, sweet potato, rice, millet, maize, cassava, soybeans, yam and sorghum\textsuperscript{3,10,11}. The damage to crop plants caused by termite pests in many African countries is not quantified. For example, in Kenya, Namibia and South Africa, where termites were reported among the key maize damaging insects which cause reduction in yield, though no exactly figures of crop loss were reported\textsuperscript{29,31}. Although it is difficult to find reliable information of crop losses in figures (percent), but still there are few scientific findings showing crop yield loss in percentage as presented in Table-1.

Damage caused by termites in other infrastructures

In tropical and subtropical countries, the destruction of buildings due to the termites have been reported as a major challenge due to the diversity of termites favored with good conditions in these geographical areas.

For instance, Africa herself has over 664 distinct termite species\textsuperscript{12,13,38}. Generally, in Africa scientific evidence on annual losses caused by termite damage in buildings are almost not available. But still, termites continue to destroy buildings which cost the owners for repairing and maintaining their buildings. In Southern Africa, especially in Zambia there is a wide infestation and termite damage in buildings\textsuperscript{38}.

This is in agreement with assertions by the reports of other scholars. For example, a research report has showed that 10 % of the budget from Building Research Institute is used for repairing damaged wooden components in buildings and buying synthetic chemicals to control termites in Western Africa\textsuperscript{16}. Apart from damaging wooden structures in buildings, also termites attack live trees of economic importance. Vividly, it is indicated that Ugandan small scale farmers suffer from termite attack in their \textit{Gravilea robusta}’s farms and the affected trees die before reaching maturity, leading to low timber production\textsuperscript{8}.

Considering the economic losses done by termites in crops, trees and wooden components in buildings, there is a need to carry out further studies to investigate the appropriate management strategies which can reduce termite activities to manageable levels and avoid possible damage in farmlands and buildings.

Termite control methods

Four methods namely i. chemical control ii. cultural control iii. biological control and iv. use of insecticidal plants are known as possible methods for termite management in buildings, wooden structures, crops and trees of economic importance.

Chemical method: Synthetic pesticides are artificial made compounds which have long half-life in the environment\textsuperscript{39}. They are effective for protection of termites though they cause serious human health and environmental problems\textsuperscript{40,42}. For instance, when methyl bromide is sprayed, it penetrates quickly inside the wooden structures and kills either dry wood termites or arboreal species\textsuperscript{5}. Although methyl bromide control termites successfully, it is believed to cause atmospheric ozone layer depletion\textsuperscript{6,43}. The ozone layer depletion turns into skin cancers which stands as a human health problem\textsuperscript{44}. Other industrial chemicals that have been used for controlling termites in stored wood, wooden components in buildings and crops are chlorpyrifos, fipronil, bifenthrin, imidacloprid, endosulfan, lindane, aldrin, coldrane, dieldrin, endrin and heptachlor\textsuperscript{43,45,47}. Chemical residues of these compounds are usually carried away from their sources by air and water to aquatic and terrestrial systems. For example, decrease by 80 % in fishes has been reported in different farming seasons of paddy cropping in Malaysia\textsuperscript{48}. Synthetic pesticides have caused insect population reduction in United States of America\textsuperscript{49} and bird populations in India\textsuperscript{50}. Furthermore, synthetic pesticides have been reported to have negative effects to human health such as cancer\textsuperscript{51}. In addition, synthetic pesticides have ability to cross cell membrane into the cells and result into cancer cells\textsuperscript{52}.  

\textsuperscript{1} Ref. 320 – 6063  
Res. J. Agriculture and Forestry Sci.

International Science Community Association
Also they cause hardness in breathing, skin pill off, vomiting, stomach ache and disrupt hormonal balance system in humans and wildlife\textsuperscript{3,34}. Although one may apply synthetic chemicals on farms and protect crops from insect pests and diseases but on the other hand they affect and kill massive non-targeted organisms / biodiversity (Figure-7).

Considering the effects synthetic pesticides on human, environment and non-target insects, there is a need to develop new approaches to control termites in sustainable and eco-friendly ways. Therefore, this study suggests to use cultural control, biological method and insecticidal plants to control termites since these methods they have no negative effects to non-targeted organisms, environment and human health as well.

**Cultural control:** Cultural control refers to indigenous knowledge. Indigenous knowledge is the knowledge and skills that is not obtained from research findings and is normally practiced locally in rural areas\textsuperscript{55}. Indigenous knowledge is much common and it has been used for a long time in developing countries before an invention of synthetic pesticides\textsuperscript{53,56}. Many African countries practice different local methods in trying to reduce termite incidence. For example, in Uganda, Kenya, Zambia, Malawi, Mozambique and Nigeria small scale farmers use cow’s urine, fresh cow dung, goat dung, dead animals, meat, fish viscera and sugarcane husks to reduce termite destruction on wooden properties and agricultural crops such as maize\textsuperscript{4,33,57,58}. Moreover, wood ashes are commonly used to control termites on crop fields and buildings in Kenya, Uganda and Zambia\textsuperscript{11,36,59}. In Tanzania, farmers use wood ashes to suppress insect pests in stored cereals, groundnuts and common beans\textsuperscript{60}.

Intercropping system strategy is highly appreciated in Uganda. For example, in this country, farmers experienced low termite damage on maize in maize - soybean intercrop system\textsuperscript{10}. This is similar with the results obtained in Zambia thereby it showed a reduced termite attack to maize crop in intercropped maize with legumes\textsuperscript{61}. To farmers, cultural control strategy is less effective because usually crops are not free from insect pests and diseases, but it is of beneficial practice to non-targeted organisms / biodiversity (Figure-7). Therefore, it is important to put into consideration these indigenous practices because there are information gaps which call for further scientific researches to justify the mechanism behind of these methods in protecting agricultural crops, trees of economic values and wooden materials in buildings from insect pests and termites.

**Biological method:** Biological method of insects is defined as natural enemies manipulations (i.e. pathogens, predators and parasitoids) for maintaining, reducing or eliminating insect pest populations from areas of interest, for example in cropping farms\textsuperscript{62,63}. Majority of scientists and researchers prefer this strategy because it is environmental - friendly method and affects only target species\textsuperscript{64}. Bacteria, viruses, nematodes, protozoa and fungi are potential biological agents for integrated pest management (IPM)\textsuperscript{55,66}. Every agent mentioned here is very important and can be applied as alternative method to synthetic pesticides. Therefore, the introduction of bacteria or fungi in bio-control have to be put into consideration for controlling insect pests in eco-friendly way resulting to the maintenance of biodiversity and good crops (Figure-7).

In this review our focus has been only on three biological control agents namely; fungi, nematodes and bacteria.

**Fungal application:** Fungal agents are entomopathogens which can be produced massively and have ability to affect the target species through contact\textsuperscript{65}. The \textit{Paecilomyces} sp., \textit{Beauveria bassiana}, \textit{Isaria fumosorosea} and \textit{Metarhizium anisopliae} are potential candidates of fungi species in the management of termites\textsuperscript{67,68}. A fungus \textit{Isaria fumosorosea} has caused a significant mortality of termites, \textit{Coptotermes formosanus} in the laboratory\textsuperscript{67}. \textit{Metarhizium anisopliae} has shown a remarkable degree of mortality on subterranean termites, \textit{Globitermes sulphureus} compared with \textit{Beauveria bassiana} and \textit{Paecilomyces} sp. in Malaysian laboratory\textsuperscript{68}. This corresponds to the research data which revealed that high efficacious mortality of tea termites, \textit{Microtermes obesin vitro} was induced by \textit{Metarhizium anisopliae} while \textit{Beauveria bassiana} demonstrated better results in field condition, India\textsuperscript{69}. This could be attributed by the highest repellency of \textit{Metarhizium anisopliae} compared with \textit{Beauveria bassiana} strains. For example, documented information has proven that the virulent strains of \textit{Metarhizium anisopliae} possess repellent properties which trigger alarm, isolation and defensive reactions among untreated termites\textsuperscript{70,71}. Based on this background information, more research designs about strain selections of fungi to control termites under field conditions are recommended.

**Nematode application:** Families Steinernematidae, Heterorhabditidae, Allantonematidae and Mermithidae belong to nematodes\textsuperscript{64}. Among these, Heterorhabditidae and Steinernematidae families have diverse species which are potential the management of terrestrial insect pests\textsuperscript{64,72}. Species of these families have a tendency of forming a mutualistic association with bacteria called nematode-bacteria complex, thereby the association is useful in infecting host insects\textsuperscript{73,74}. At infective juvenile stage, nematodes become active and free living that are able to search for host insects. Wherever they get host insects, they use open space like mouth and anus to penetrate into haemocoel of host insects and release their mutualistic bacteria\textsuperscript{75,76}. Usually, the released bacteria produce lethal toxins which cause fatal septicemia and death to host insect. The host cadaver is used to serve as source of food in reproducing another infective juvenile generation of nematodes\textsuperscript{77}.

Few studies have been conducted to study the potentiality of nematodes on termite control. For example, high mortality has been found to termites, \textit{Reticulitermes flavipes} exposed to parasitic nematodes\textsuperscript{78}.
A study conducted in Benin using parasitic nematodes such as *Heterorhabditis sonorensis* and *Heterorhabditis indicus* showed a significant mortality to subterranean termite, *Macrotermes bellicosus* in laboratory. This is in line with the laboratory report which justified that nematodes; *Steinernema feltiae* (Filipjev-UK76), *Heterorhabditis bacteriophora* (Poinar - HP88), *Steinernema carpocapsae* (Weiser-Mexican 33) and *Steinernema riobrave* (Cabanillas, Poinar, and Raulstonn - 355) are able to cause severe mortality in termites of *Reticulitermes flavipes* (Kollar), *Gnathamitermes perplexus* (Banks) and *Heteroterme aureus* (Synder). Apart from laboratory trials, also experiments under field conditions have been done. A study under field conditions concluded that nematodes, *Steinernema carpocapsae* alone can control termites, *Reticulitermes tibialis*. This is related to study designed to use nematodes in eliminating termites of *Odontotermes obesus* from millet and wheat crops. Again it remains a challenge to researchers because high rates of reports are laboratory based and very few successes from field trials. Further studies are required so as to identify the limitations that hinder entomopathogenic nematodes in controlling or eliminating termites under the field conditions.

**Bacterial application:** Some rhizobacteria are good sources of Hydrogen cyanide for example, *Pseudomonas aeruginosa*. The Hydrogen cyanide is the chemical compounds which is effective in the management of desirable soil microorganisms. For example, Hydrogen cyanide from *Pseudomonas aeruginosa* has served as agent control towards nematodes in the fields. All nitrogen cyanide - producing rhizobacterial species can be very useful to termite control by applying them directly to the termite mounds, thereby localizing cyanide production and also to minimize menaces effects on other soil living animals. Bacteria which produce harmful metabolites may play part in biological control of termites. For instance, three different hydrogen cyanide - producing rhizobacterial species, *Aeromonas caviae*, *Alcaligenes latus* and *Rhizobium radiobacter* have been tested under *in vitro* conditions and demonstrated positive results to kill termites of *Odontotermes obesus*. Although, less information is available on negative effects of Hydrogen cyanide released from rhizobacterial species, therefore, this review proposes numerous studies to investigate the negative effects of Hydrogen cyanide (HCN) to other living soil fauna compared with conventional insecticides.

**Use of insecticidal plants:** Insecticidal plant compounds occur naturally, degrade easily when exposed to the sunlight and therefore have short half-life of persistence to the environment. Generally, plant pesticides are known to control insect pests in eco-friendly way because they do not have negative effects on non-targeted insects, human health, environment and crops. Studies show that compounds derived from plants usually degrade into harmless substances ranging from few seconds, hours and even a day. On the other side, synthetic pesticides are known to have negative effects on beneficial insects, human health, environment and insect pests do resist to them which lead to their failure in controlling insect pests. Due to undesirable effects of synthetic pesticides, much attentions have been taken in developing alternative methods such as use of insecticidal plants so that to minimize health and environmental problems.

In Africa and other developing countries, different insecticidal plants have been reported to be effective in controlling insect pests both in field crop and stored products in different crops. For instance, candidate pesticidal plants that are applied by Ugandan farmers in the control of insect pests on biomass of the Lake Victoria are *Phytolacca dodecandra*, *Cofea species*, *Carica papaya*, *Cupressus spp.*, *Tagetes spp.*, *Nicotiana tabacum*, *Capsicum frutescens*, *Tithonia diversifolia*, *Lantana camara*, *Mus spp.*, *Aloe spp.*, *Tephrosia vogelii*, *Eucalyptus spp.*, *Moringa oleifera*, *Azadirachta indica* and *Vernonia amygdalina*. In Tanzania, farmers have been applying a mixture of powdered rice husks and neem parts, mixture of soap solvents and neem components, neem parts mixed with cow’s urine, combination of red pepper, tobacco and neem components. Several scholars support the use of insecticidal plants with some modified application techniques. For instance, appreciated positive results have been obtained in the test involving fresh ground leaves, mixed and soaked overnight. A boiled combination of detergent soap and parts of pesticidal plants has demonstrated positive results in the control of insect pests. Another technique involving soaking of the sun dried plant materials into organic solvents (acetone) has shown some promising results in protecting leaves of crop plants from rust problem in both field and greenhouse conditions. All mentioned techniques show efficacious results in controlling some pest insects. This calls for diverse research approaches to assess the effective application method. For example, what will happen when plant parts are boiled or soaked in soap solution and organic solvents with the aim of wider scale application on the termite and insect pest control.

**Potential of Cupressus lusitanica, Tephrosia vogelii, Eucalyptus dalrympleana, Lantana camara and Azadirachta indica in controlling termites:** Five plant species including *Cupressus lusitanica*, *Tephrosia vogelii*, *Eucalyptus dalrympleana*, *Lantana camara* and *Azadirachta indica* are selected as potential candidates in controlling termites. The selection of these botanicals has been done due to their efficacious results demonstrated in management of insect pests and termites on field crops, stored food cereal and legume grains as well as wooden properties. In developing countries especially in the villages, these botanicals are used to control insect pests and termites in agricultural crops, stored grains and wooden properties. Therefore, it is of paramount important to conduct researches that serve for rising awareness of people especially farmers and households on how to use the locally available pesticidal plants in the control of insect pests.
Cupressus lusitanica: Cupressus lusitanica (mexican cypress) belongs to the family cupressaceae and possesses aromatic compounds and essential oils such as β-cedrene, bornyl acetate, α-cedrene, epimanool, cedrol and agathadiol as depicted in Figure-2. Essential oils possess antimicrobial, antifungal and insecticidal properties. Growth inhibition has been observed to Aspergillus niger and Bacillus cereus after exposing to volatile essential oils. Other studies, found that essential oils have a fumigant and repellency effects against insect pests in stored food grains. In addition, leaf extracts and leaf powders are used to protect crops from termites. This body of knowledge might be useful for insect pests and termite pests control in field crops, buildings, wooden structures and trees of economic importance. Therefore, many more studies are required to identify the active compounds from Cupressus lusitanica and test their efficacy to insect pests including problematic termites.

Figure-2: Some terpenic compounds in Cupressus lusitanica.

Eucalyptus dalrympleana: There are many varieties of eucalyptus species which belong to the family myrtaceae. Eucalyptus dalrympleana and other Eucalyptus spp. have strong essential oils including, aromadendrene, limonene, α-pinene, 1,8-cineole, p-cymene, α-terpineol, citronellyl acetate, eucamalol, linalool, γ-terpinene and citronellal. Among these components, the 1, 8-cineole has been reported as the most active monoterpane. Many studies have reported similar results on 1, 8-cineole as shown in Figure-3. The study which used oil components of synthesized 1, 8-cineole and natural monoterpenes founda fumigant toxicity against Musca domestica(L.). In addition to this, severe mortality of first-instar nymphs of Rhodnius prolixus has been observed when introduced into volatile essential oils and monoterpenes composed of 1, 8-cineole.

Moreover, the extracts of 1,8-cineole from Eucalyptus dalrympleana is effective for the reduction of Haematobia irritans (Horn fly) incidence in cattle. Other scholars have quantified that essential oils from Eucalyptus dalrympleana have insecticidal and repellent activity against stored food grains insect pests. Similarly, essential oils of Eucalyptus dalrympleana have shown antifeedant, repellency and insecticidal properties on termite workers of the Odontotermes obesus. Based on these findings, essential oils could be useful in the management of insect pests, flies and termites. However, essential oils are very volatile compounds which are difficult to handle them, meaning that they can escape easily when exposed to sun light. Any study to investigate essential oils stability should be done with the purpose of improving their half-life so that to minimize the frequent application.

Tephrosia vogelii: Tephrosia vogelii is a legume which belongs to the family Fabaceae. Tephrosia vogelii is the most effective insecticidal plant which is used in the management of insect pests in both field crops and stored products. It is also used to increase soil fertility through biological nitrogen fixation. The effectiveness of Tephrosia vogelii is due to bioactive compounds such as chemotype 2 (C2) and chemotype 1 (C1) (Figure-4). C1 has been reported to be the most effective compound in Tephrosia vogelii resulting to the repellency of insect pests. For these reasons, the pesticides from Tephrosia vogelii possess insecticidal effects. For example, the pesticides from Tephrosia vogelii are commonly used in remote areas of Africa for illegal fishing. The pesticides from Tephrosia vogelii were already confirmed to exhibit antifeedant, repellent and insecticidal properties towards golden flea beetle.

In Malawi, Mozambique and Zambia, farmers who used extracts from crushed leaves of Tephrosia vogelii managed to protect field crops from termites. However, there are inadequate scientific studies to verify the potentiality of using Tephrosia vogelii to control problematic termites. Therefore, there is an urgent need to identify other bioactive compounds of Tephrosia vogelii which may control termites effectively.

Figure-3: Chemical structure of 1,8-cineole.

Figure-4: Chemotype 1 (C1) and Chemotype 2 (C2).
Azadirachta indica: Azadirachta indica is a native plant in India\textsuperscript{115}. It belongs to Meliaceae family with known more than 200 compounds\textsuperscript{39}. Among these compounds, Azadirachtin is the most active constituent in A. indica compared with salannin and nimbin (Figure-5). Azadirachtin has strong repellent, antifeedant and insecticidal effects to insects. Azadirachtin has ability to interfere chemoreceptors, block sugar and receptor cells, affect growth and moulting, affect reproduction through inhibiting oogenesis and ovi position in female and interrupt mature sperm production in male insects\textsuperscript{39}. Documents on A. indica support the botanical use of this plant. For example, a practical report has reported that the A. indica extracts have strong antifeedant effects against termites, Reticulitermes speratus\textsuperscript{116}. Similar studies have been conducted using different species apart from termites. For instance, it has been found that A. indica extracts strongly inhibited growth in Pseudaletia unipuncta and Trichoplusia ni, after laboratory exposure\textsuperscript{117}. The A. indica oil extracts minimized significantly the number of Tuta absoluta in vegetable tomatoes compared with the fields without treatments\textsuperscript{118}. Thereafter, it is worthy to use A. indica extracts as alternative to control insect pests and termites which are serious menace to plants.

![Image of chemical structure](image1)

**Figure-5**: Some of chemical structures in Azadirachta indica\textsuperscript{119}.

Lantana camara: Lantana camara is a native plant of South America and it belongs to Verbenaceae\textsuperscript{120}. Apart from South America, it is invasive plant to other areas\textsuperscript{121}. Some scholars have recognized and presented that Lantana camara possesses diverse compounds including proteins, carbohydrates, lactones, furfural, flavonoids, triterpenoids, glycosides, flavonoids, and phenylethanoid glycosides\textsuperscript{120,122}. Among these chemical compounds, triterpenoids such as ursolic acid stearoylglucoside is reported to be more active component than any other in this plant, as illustrated in (Figure-6)\textsuperscript{123}. The presence of ursolic acid stearoylglucoside and others have enhanced many medicinal applications and few of them have been discussed here. Exposing rats or mice to Lantana camara affected their ability to move, caused congestion of heart and lung, nephrosis, dehydration and constipation with hepatosis as well as low reproduction performance according\textsuperscript{123,124}.

![Image of chemical structure](image2)

**Figure-6**: A chemical structure of ursolic acid stearoylglucoside\textsuperscript{128}.

**Conclusion**

This review has demonstrated that termite infestation is high to less developed countries although synthetic insecticides are primarily applied to control termites. However, the continuous use of synthetic insecticides is highly discouraged since they cause human health and environmental problems. Therefore, it is necessary to combine or integrate two or more pest control systems which are environmentally friendly in order to minimize the negative effects caused by synthetic chemicals. In addition, more research is needed regarding the active botanical ingredients, preparation requirements, application rates and residue effects to the environment and health risks to the farmers and other users. Apart from insecticidal plants, on-farm research is required in biological and cultural control for feasible management of termites at farmer level.

**Acknowledgement**

The authors acknowledge the African Development Bank (ADB) for funding this study under the permission of the Nelson Mandela African Institution of Science and Technology (NM-AIST). Gratefully, we thank the Tropical Pesticides Research Institute of Arusha through Mr. Maneno Chidege for his expertise in identification of termite images. A lot of thanks to Mr. Kafula Chisanga from Zambia Agricultural Research Institute for his advice and constructive comments in enriching this work.
Figure-7: Termite management practice model and its effect on crop and biodiversity. In this model, four methods with regard to management have been described. In group 1, the termite management option leads to very health biodiversity and good crops; group 2, termite management option leads to health biodiversity and good crops; in group 3, termite management strategy results to bad crops and very health biodiversity while in group 4, termite control option causes very bad biodiversity and good crops.
